Imaging of the pancreas: Part 2

Keith Quencer, MD, Avinash Kambadakone, MD, FRCR, Dushyant Sahani, MD, and Alexander S. R. Guimaraes, MD, PhD

In Part 2 of this two-part article, the authors discuss imaging manifestations of various abnormalities affecting the pancreas.

Diagnosis of pancreatic conditions is a challenge to physicians due to the anatomical location of the organ deep within the abdomen.

Imaging with multidetector computed tomography (MDCT) and magnetic resonance imaging (MRI) along with the use of 3-dimensional (3D) imaging play a critical role in the evaluation of pancreatic diseases.

Specific types of pancreatitis

Groove pancreatitis

This rare form occurs in the spaces between the head of the pancreas, the second portion of the duodenum, and the CBD. The inflammatory involvement results in scar-tissue formation in the pancreatico-duodenal groove and subsequent cystic dystrophy of heterotopic pancreatic tissue in the duodenal wall.[6,16] Imaging features include inflammatory involvement of the pancreas and medial wall of the duodenum, with cystic changes limited mostly to the pancreatico-duodenal groove (Figure 10). Groove pancreatitis can occasionally mimic pancreatic adenocarcinoma given its focal nature, its propensity to cause strictures of the bile and pancreatic ducts, and its fibrotic character, which leads to decreased enhancement and T1 hypointensity. Findings favoring groove pancreatitis over adenocarcinoma include cystic changes within the lesion, smooth rather than abrupt narrowing of the pancreatic and CBD, and a sheet-like mass rather than a rounded mass.

Dr. Quencer, Dr. Kambadakone, Dr. Sahani, *and* ***Dr. Guimaraes*** *are at the Division of Abdominal Imaging and Intervention, Massachusetts General Hospital, Boston, MA.*

Autoimmune pancreatitis

Autoimmune pancreatitis, first described in 1995, is pathologically characterized by dense inflammatory infiltrates of lymphocytes and plasma cells around the small- to medium-sized pancreatic ducts with associated fibrosis. The clinical presentation is similar to pancreatic cancer, with weight loss and obstructive jaundice, but presents with the absence of severe attacks of abdominal pain seen with acute pancreatitis. Extrapancreatic manifestations are observed in 19% to 50% of cases and include multifocal biliary strictures, renal lesions from tubulointerstitial nephritis, retroperitoneal fibrosis, Sjogren's syndrome, and inflammatory bowel disease (Figures 11 and 12). Serum IgG4 levels are characteristically elevated and a level > 135 mg/dL is 95% accurate and 97% specific in making the diagnosis. Elevation of IgG4 is rare in pancreatic cancer and is observed only in 10% of cases. A combination of imaging findings, serologic, or histologic criteria are necessary to diagnose autoimmune pancreatitis (Table 3).[17-19]

Autoimmune pancreatitis has typical imaging features. Classically it is described as diffuse pancreatic enlargement, which becomes featureless secondary to loss of normal pancreatic lobulations, foreshortening of the pancreatic tail and a peripheral rind or 'wrapping' around the pancreas, which appears hypodense on CT and as hypointense on both T1 and T2 images (Figure 13). Pancreatic ductal irregularities are often seen as ductal strictures or diffuse narrowing.[20] Autoimmune pancreatitis can also present as a focal mass, which often poses a diagnostic dilemma (Figure 14). The differences and similarities in imaging features of focal autoimmune pancreatitis and pancreatic adenocarcinoma are listed in Table 4.

Tropical pancreatitis

A chronic form, tropical pancreatitis has unique clinical, epidemiological and imaging features. It characteristically presents at a young age (mean age 12.5 years, M:F, 1.6 to 5:1), leads to early development of diabetes, has a specific geographic distribution (India, Asia, South America), and is associated with malnutrition, which is thought to be a cause, not an effect. Another potential etiology is a mutation of the serine protease inhibitor Kazal type 1 (*SPINK1*) gene.[21] On imaging, there is significant atrophy of the pancreas, marked dilatation of the pancreatic duct, and large intrapancreatic ductal stones,

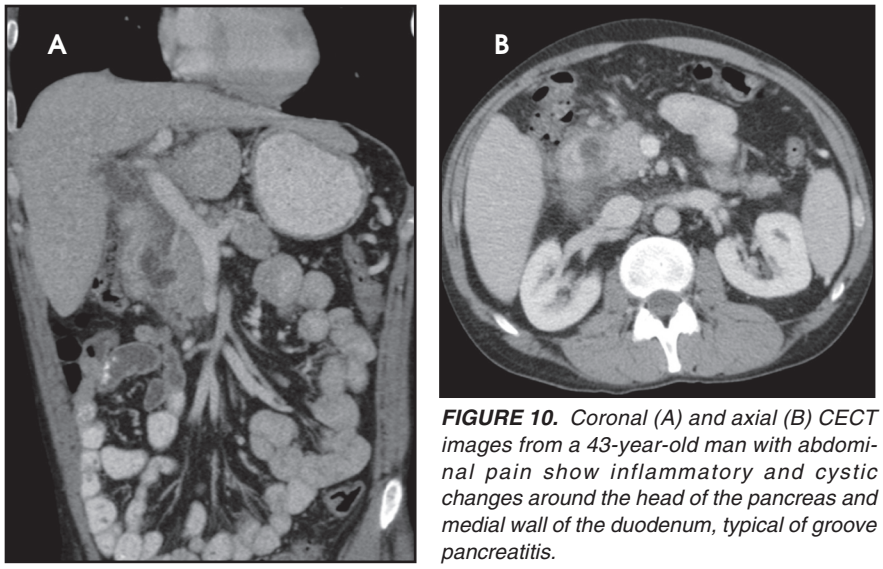

FIGURE 10. *Coronal (A) and axial (B) CECT images from a 43-year-old man with abdominal pain show inflammatory and cystic changes around the head of the pancreas and medial wall of the duodenum, typical of groove pancreatitis.*

which have been reported up to 5 cm in size. This disease is associated with a marked predisposition to pancreatic adenocarcinoma, which occurs at an early average age of 45 years.[6]

Pancreatic neoplasms

Cystic pancreatic lesions

Increased utilization of cross-sectional imaging, such as MDCT and MR, has led to an increased detection of cystic pancreatic lesions with nearly a third of cases being diagnosed in asymptomatic patients (Tables 5 and 6) and a prevalence of incidental cystic lesions on CT being present in 2.6% of examinations.[22] Despite the significant overlap in the imaging features of pancreatic cystic lesions, MDCT and MRI are fairly accurate in the characterization of these lesions. Occasionally, EUS with or without aspiration/biopsy might be necessitated for characterization prior to surgical intervention.

Intraductal papillary mucinous neoplasm (IPMN)

IPMNs are commonly encountered cystic lesions of the pancreas and can be classified based on involvement of the main duct and side branch. There is the main duct IPMN, side branch IPMN, and combined IPMN (involving both main duct and side branch). Main duct IPMNs cause diffuse enlargement of the pancreatic duct and do not present as cystic lesions of pancreas. Up to 40% of main ducts IPMNs have malignant features at diagnosis and they are often surgically resected. The features on imaging suggestive of malignancy in main duct IPMNs include enhancing mural nodules or main duct dilatation > 1 cm. On the other hand, side branch IPMNs (also known as branch duct IPMNs) are less likely to be malignant and are often followed up on serial imaging. Side branch IPMNs have a macrolobulated or 'cluster of grapes' appearance on imaging. The most characteristic imaging feature is the communication of the lesion with the main pancreatic duct, which differentiates them from mucinous cystic neoplasms. A typical finding on ERCP is the so called 'bulging papilla' secondary to increased mucin production by the lesions. Demonstration of communication with the pancreatic duct with MRCP or ERCP is of paramount importance in diagnosing IPMNs as this limits the differential diagnosis of a cystic lesion to IPMN and pseudocysts, which are the only other cystic lesions to demonstrate ductal communication. Surgical resection is performed in symptomatic patients or in those lesions that demonstrate suspicious features on follow up imaging, such as enhancing mural modules, a size > 3cm and concomitant main pancreatic ductal dilatation.[2,23] In asymptomatic patients with side branch IPMNs measuring < 3 cm without solid nodules, follow-up imaging is recommended for detection of suspicious features.

FIGURE 11. *Curved reformatted coronal CECT image before treatment with steroids (A) shows a swollen, foreshortened and somewhat hypoenhancing , edematous pancreas. After treatment (B), these changes are no longer present. The presence of biliary stricture led to placement of a biliary stent (white arrows). This patient was serum IgG4 positive.*

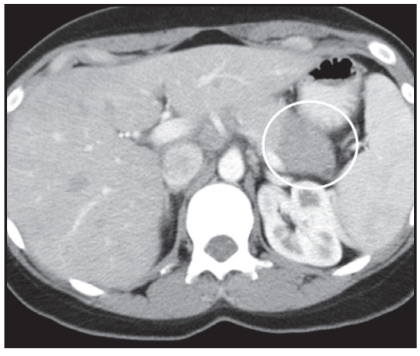

FIGURE 12. *Axial CECT image in a 29-year-old woman shows a focal hypodense well circumscribed pancreatic tail mass (white circle) with loss of pancreatic lobulations. The patient was serum IgG4 negative. The mass was resected and the pathologic specimen was consistent with autoimmune pancreatitis.*

Serous cystadenoma (SCA)

Also known as microcystic adenomas, serous cystadenomas do not have malignant potential. Therefore, resection is only indicated when they become

Table 3. Diagnostic Criteria for Autoimmune pancreatitis*

Imaging	Serum	Histology
Diffusely enlarged pancreas	Increased IgG4	Lymphoplasmacytic infiltration or fibrosis around pancreatic or biliary ducts
Hypoattenuating peripheral rim	Increased IgG or gamma globulin	Increased number of IgG4 positive plasma cells
Pancreatic duct narrowing (can be focal, segmental or diffuse)	Presence of specific autoantibodies	Pulmonary or salivary gland lymphplasmacytic infiltration with IgG4 positive plasma cells

*Criteria used by the Japan Pancreas Society for the diagnosis of autoimmune pancreatitis. To establish the diagnosis at least one imaging and one serum or histologic finding has to be present. Specific serum antibodies include antilactoferrin antibody (ALA), anti-carbonic anhydrase II antibody (ACAII), anti-smooth-muscle antibody (ASMA), and antinuclear body (ANA). [19]
IgG= Immunoglobulin G

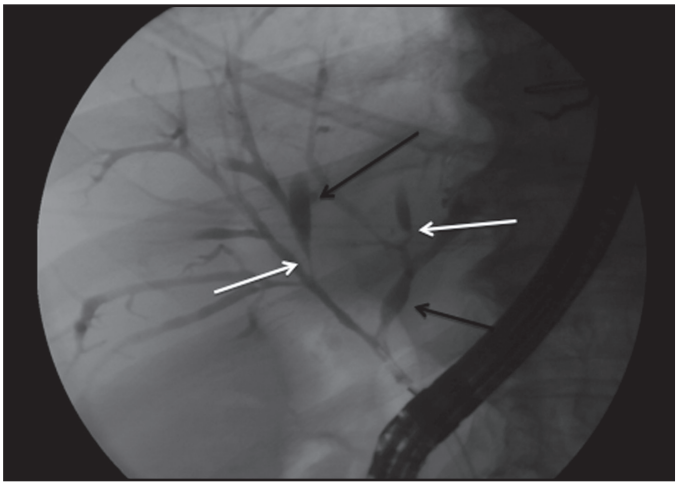

FIGURE 13. *Single ERCP image shows one of the most common extrapancreatic manifestations of autoimmune pancreatitis, multifocal intrahepatic biliary strictures (white arrows), and dilations (black arrows). These imaging findings are similar to those of primary sclerosing cholangitis (PSC), but unlike PSC, are reversible with initiation of steroid therapy.*

FIGURE 14. *Single axial CECT image in a 61-year-old man with autoimmune pancreatitis shows multifocal hypodense renal lesions. These lesions reversed with steroid therapy. Renal lesions are another frequently seen extrapancreatic manifestation of autoimmune pancreatitis.*

Table 4. Imaging differentiation between focal AIP (autoimmune pancreatitis) and adenocarcinoma.

Present in pancreatic adenocarcinoma and focal AIP	Focal enlargement Loss of normal pancreatic contour/lobulations Biliary ductal dilation from CBD narrowing Hypoenhancement compared to normal parenchemya
Suggesting focal AIP over adenocarcinoma	Hypodense/hypointense periphery around pancreas Narrowing of pancreatic duct Smooth, tapered narrowing of CBD Decrease in size after steroid therapy Characteristic extrapancreatic manifestations (renal lesions from tubulointerstitial nephritis, enhancement of the wall of the CBD, PSC type multifocal narrowing of the intrahepatic bile ducts)
Suggesting adenocarcinoma over focal AIP	Arterial/vascular encasement Pancreatic ductal dilation Atrophy of proximal pancreatic parenchemya Shouldered/abrupt narrowing of the CBD

Table 5. Common cystic pancreatic lesions

Pseudocysts	Common. Lined by granulation tissue rather than epithelium. Contain pancreatic debris, blood. Seen in patients with hx of pancreatitis. Takes 4 weeks to form.
Side Branch IPMN	Common. Can have cluster of grapes appearance. Demonstrates communication to main pancreatic duct on MRCP -> management.
Serous Cystadenoma	Rare. Benign. Multiple small cysts. Predilection for pancreatic head. May have central scar containing calcification.
Mucinous Cystic neoplasm	Rare. Malignant potential. Treated with surgical resection. Few, large cysts, thick septations. Predilection for pancreatic tail. May have peripheral calcifications.
Cystic Neuroendocrine Tumor	Rare. Cystic degeneration from necrosis. Walls have not undergone necrosis and demonstrate avid enhancement.
SPEN	Rare. Malignant potential -> surgical resection. Occurs in younger females. Mixed solid and cystic lesion.
True Cysts	Very rare. Lined by epithelium. Seen in PCKD, VHL and CF

PCKD=polycystic kidney disease, VHL=von Hippel-Lindau, CF=cystic fibrosis, SPEN= solid-cystic papillary epithelial neoplasm

Table 6. Classification of cystic pancreatic lesions

Morphology	Potential Etiologies
Unilocular Cysts	Pseudocyst Unilocular serous cystadenoma IPMN True cysts
Microcystic	Serous cystadenoma (AKA microcystic adenoma)
Macrocystic	Mucinous cystadenoma IPMN Oligocystic variant of serous cystadenoma
Cyst with solid components	Solid pseudopapillary tumor Mucinous cystadenoma IPMN Cystic degeneration of solid neoplasm (pancreatic endocrine tumor, pancreatic adenocarcinoma, metastasis)

IPMN= intraductal papillary mucinous neoplasm

symptomatic due to mass effect. They typically affect older females and are associated with von Hippel-Lindau disease. SCAs favor the pancreatic head and are composed of multiple tiny cysts (> 6 cysts measuring 1 mm to 2 cm). Characteristically, these lesions will have a central scar, which can sometimes calcify and has a predilection for the pancreatic head. These lesions may grow up to 4 mm per year. The diagnosis of a serous cystadenoma can be made with confidence when a lesion demonstrates the classic imaging appearance of a multilobulated external border, thin enhancing septa in a honeycomb-like appearance, and a central scar, which occasionally calcifies. Atypical appearances can be seen. For example, occasionally the cysts can be too small to resolve even with MRI or high-frequency EUS and appear to have a solid appearance. Additionally, these lesions, instead of having numerous tiny cysts, can have a few larger cysts (oligocystic or macrocystic variant), lack a central scar and can be located in the pancreatic body or tail, and therefore mimic a mucinous cystic neoplasm. EUS-guided aspiration can confirm the diagnosis in atypical cases by establishing the presence of glycogen rich epithelial cells and absence of mucin.[2,24]

Mucinous cystic neoplasm

Also known as mucinous macrocystic neoplasm, these lesions, unlike their microcystic counterparts, have malignant potential or are frankly malignant at diagnosis. Therefore, surgical resection is indicated. These lesions demonstrate a 9:1 female-to-male incidence. They are more common in the pancreatic tail and contain a few large mucin-containing cysts (< 4 cysts larger than 2 cm). On imaging, these lesions tend to have a smooth outer contour and a few septae, which can occasionally be enhancing and thick (Figures 15 and 16). Enhancing nodular and papillary projections may occasionally be seen. When suspected, EUS aspiration will be performed before surgical excision to exclude other cystic lesions, including a pseudocyst and serous cystadenoma. The fluid aspirated will contain thick mucin and an elevated level of tumor markers, such as carcinoembryonic antigen (CEA) and CA-19-9.[1,24,25]

Cystic neuroendocrine tumors

Neuroendocrine tumors, as discussed below, can sometimes undergo cystic degeneration and mimic a cystic neoplasm. The outer wall of the lesion will often be spared from cystic degeneration and therefore demonstrate features consistent with neuroendocrine tumor, specifically avid early enhancement (Figure 17).

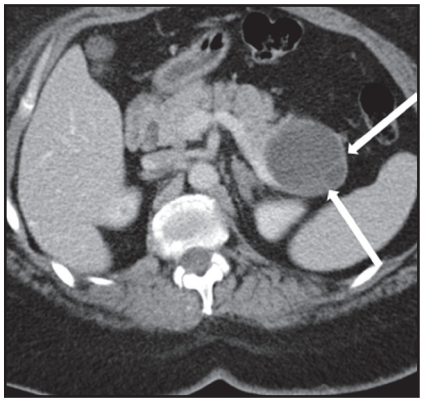

FIGURE 15. *Axial CECT of a 56-year-old woman shows a low attenuation pancreatic tail lesion with a few scattered large septations (white arrows). The imaging findings, lesion location, and demographics are all consistent with the subsequent pathologic diagnosis of a mucinous cystic neoplasm.*

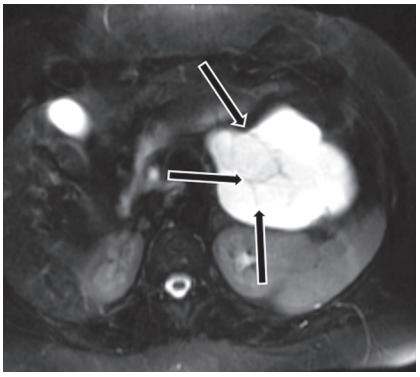

FIGURE 16. *Axial T2-MRI of a 42-year-old woman demonstrates a large T2 hyperintense lesion in the pancreatic tail with a few septations (black arrows) separating the lesions into a few large cysts. Imaging findings are consistent with a mucinous cystic neoplasm, which was subsequently proven pathologically on resection.*

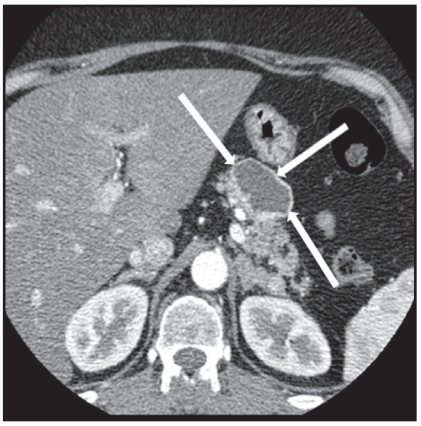

FIGURE 17. *Axial CECT image in a 50-year-old woman shows a cystic lesion in the pancreatic body with a thin peripheral rim of enhancement (white arrows). Subsequent resection showed this to be a cystic neuroendocrine tumor.*

Solid pseudopapillary tumor (SPT)

Previously known as solid-cystic papillary epithelial neoplasms (SPEN), these lesions are unique among the cystic pancreatic neoplasms in that they tend to affect young patients (20-30 yrs). Affected patients tend to be African American or Asian and female. The appearance of these lesions is varied, but they are classically large, well encapsulated, and of variable internal characteristics with areas of hemorrhagic necrosis (Figures 18 and 19). The prognosis is good with a 5-year survival estimated at 97% after surgical resection.[26]

True cyst

Unlike cystic lesions seen in other solid organs in the abdomen, true cysts are rare and almost never occur in a normal patient population. When present, true cysts are often multiple rounded and welldefined lesions. Evidence of underlying conditions, such as von Hippel-Lindau disease, polycystic kidney disease, and cystic fibrosis, are often apparent on imaging (Figure 20).

Solid pancreatic tumors

Pancreatic adenocarcinoma

With an estimated 43,140 new cases of pancreatic adenocarcinoma in the U.S. in 2010 and a 5-year-survival rate of < 5%, pancreatic adenocarcinoma is the fourth-leading cause of cancer death in the U.S. Pancreatic adenocarcinoma is primarily a disease of the elderly with 80% of cases affecting patients in the sixth or eighth decade and accounts for 95% of all malignant pancreatic lesions.[27] Surgical resection of localized tumors allows cure, but only about 15% to 20% of new cases are candidates for surgical resection at presentation. Complete resection with negative margins without lymph nodal involvement gives the best possible 5-year survival rates of up to 25% to 30%. CA-19-9 may be elevated in up to 80% of cases, but has limited sensitivity to identify patients with small tumors amenable to surgical resection. CA-19-9 is mainly useful in follow-up of patients undergoing treatment and when a rise in CA-19-9 precedes imaging manifestation. While there is an association between chronic pancreatitis, diabetes, and pancreatic adenocarcinoma, the causal relationship is uncertain. Smoking has been shown to be associated with 2 times the increased risk of developing pancreatic adenocarcinoma. While rare, it is interesting to note that rare genetic syndromes, such as familial atypical multiple mole melanoma syndrome (FAMMM), hereditary pancreatitis, and Putz-Jeghers syndrome are associated with a 20- to 130-fold increased risk of pancreatic cancer.[1]

Imaging findings

Multiphasic MDCT of the pancreas is the modality of choice for diagnosis and staging of pancreatic carcinoma and involves acquisition of images in the pancreatic phase instead of the arterial phase. MDCT has a dual role in pancreatic cancer which includes lesion detection, localization and characterization; and secondly, in the determination of tumor resectability. Although ultrasound and MRI may play a role in the initial diagnosis of pancreatic carcinoma, MDCT is preferred for diagnosis and staging. On US, they are seen as ill-defined hypoechoic lesions within the pancreas. On T1-weighted MRI, the mass will be hypointense to normal the pancreas. On both MDCT and MR, pancreatic cancer appears as a hypoenhancing mass with focal contour abnormality. The hypoenhancement is accounted for by the desmoplastic and hypovascular nature of the tumor. On dynamic images, the pancreatic phase shows the greatest attenuation differentiation and is therefore more sensitive than the portal-venous phase in detection of these lesions. However, in up to 10% of cases, pancreatic cancer can be iso-attenuating to pancreatic parenchyma, and therefore secondary signs

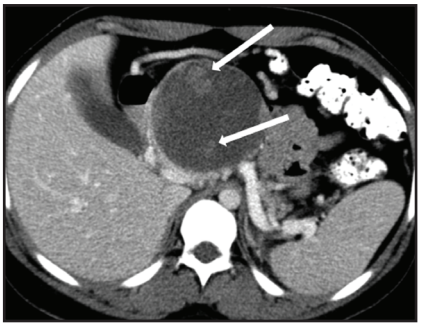

FIGURE 18. *Axial CECT image shows solid and enhancing (white arrows) as well as cystic components of a pancreatic head mass in a 19-year-old woman. Subsequent resection proved this to represent a solid pseudopapillary epithelial neoplasm for which the imaging findings and demographics are characteristic.*

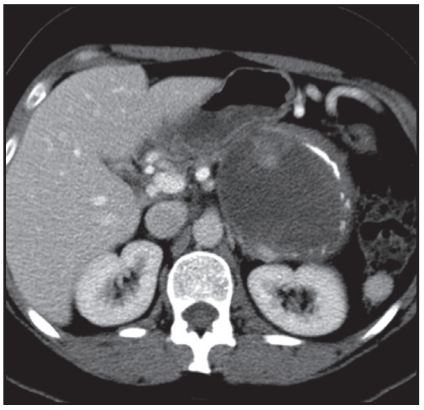

FIGURE 19. *Axial CECT shows a peripherally calcified heterogenously enhancing cystic mass in the pancreatic body and tail, which was a solid pseudopapillary epithelial neoplasm in a 33-year-old woman.*

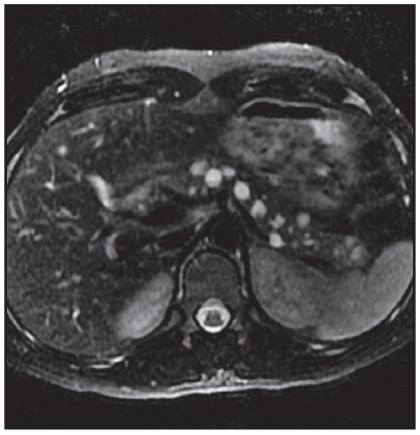

FIGURE 20. *Coronal T2-weighted images shows multiple T2 hyperintense pancreatic in a 31-year- old woman with known von Hippel-Lindau syndrome.*

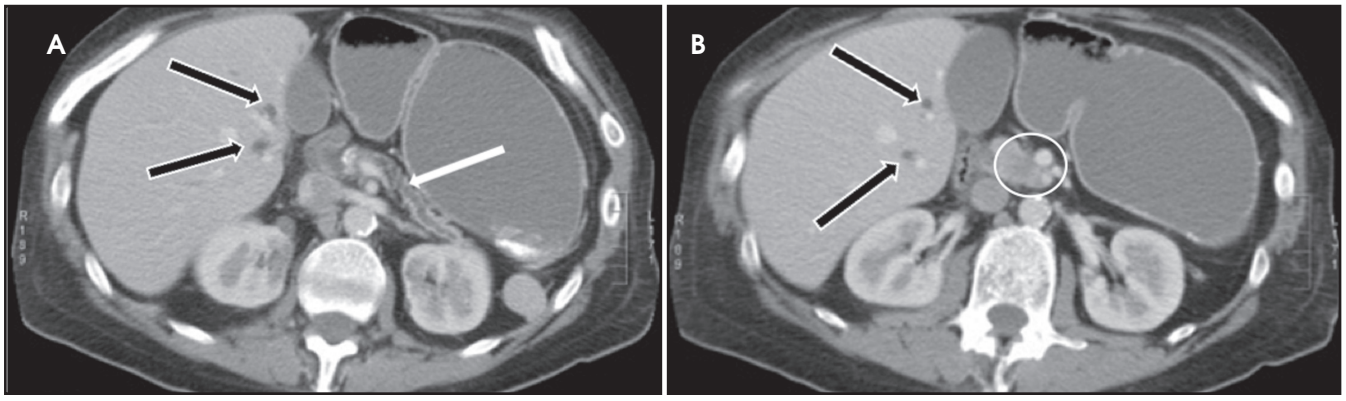

FIGURE 21. *Two axial CECT images (A and B) show dilatation of both intrahepatic bile ducts (black arrows) the pancreatic duct (white arrow), as well as atrophy of the pancreatic tail. The double duct sign and pancreatic tail atrophy were concerning findings for a pancreatic head adenocarcinoma in this 47-year-old man. The mass is subtle (white circle) but present. Careful search for the underlying mass lesion is necessary in cases showing secondary signs of pancreatic adenocarcinoma, such as dilated biliary and pancreatic ducts as well as parenchymal atrophy.*

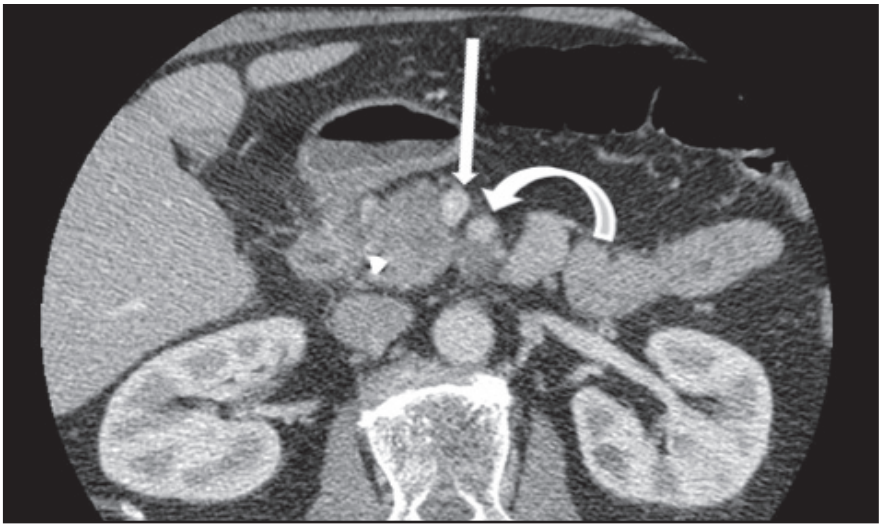

FIGURE 22. *Axial MDCT image in the pancreatic phases in a 72-year-old man shows a hypodense tumor in the pancreatic head with < 180-degree involvement of SMV (thin white arrow) and SMA (curved white arrow). By imaging criteria alone, it was considered borderline resectable. However, at surgery this pancreatic adenocarcinoma was unresectable.*

provide a clue to diagnosis. These secondary signs include pancreatic ductal dilatation and parenchymal atrophy distal to the lesion with abrupt change in ductal caliber at the site of lesion (Figure 21). While MDCT is about 95% accurate in diagnosing pancreatic cancer, approximately 5% of patients undergo surgical resection for benign disease, such as chronic pancreatitis or focal AIP. On T2W MR imaging, the lesion itself will often be inconspicuous, but secondary signs of upstream pancreatic ductal dilatation or focal contour abnormality of the pancreas may be seen.

True determination of resectability of borderline tumors will be made at the time of laporotomy. The signs of potential resectability at laparotomy include demonstration of a normal fat plane be-

Table 7. Pancreatic neuroendocrine tumors

Tumor	Prevalence amongst PETs	Malignancy Rate	Clinical Symptoms, Features
Insulinoma	40%	10%	Hypoglycemia, elevated serum C-peptide
Gastrinoma	20%	60%	Gastric hypersecretion leading to post-bulbar ulcers and diarrhea. 25% of patients have MEN1. Serum gastrin level>1000pg/mL with paradoxical increase with secretin administration. More common in duodenum than pancreas.
Non-Functioning	35%	85%	Non-specific, relate to mass not hormone production.
Glucagonoma	Rare	80%	Diabetes, dermatitis (necrolytic migratory erythema), depression, deep venous thrombosis
VIPoma	Rare	70%	"Pancreatic Cholera." Watery diarrhea, hypokalemia, dehydration.
Somatistatinoma	Rare	70%	Increased association with NF1, especially when duodenal in location.

MEN1-Multiple endocrine neoplasias-1, NF-1=Neurofibromatosis Type 1, VIP=Vasoactive intestinal peptide

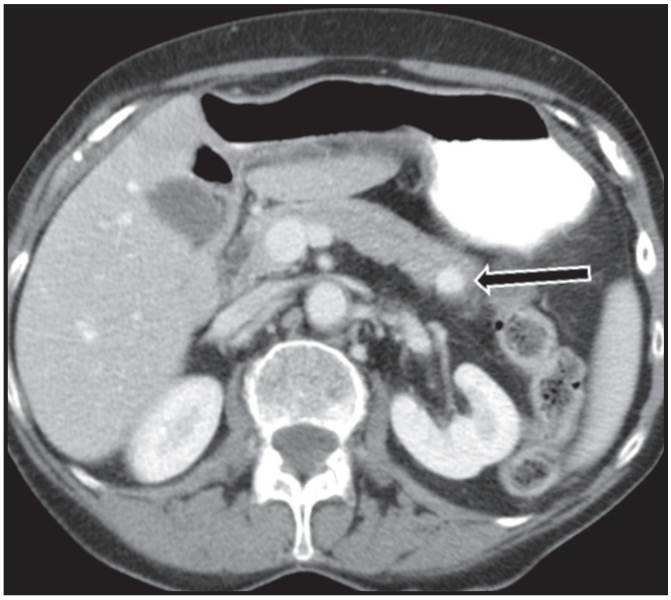

FIGURE 23. *Axial CECT image of an 81-year-old woman shows a hyper-enhancing pancreatic tail lesion (black arrow) consistent with a neuroendocrine tumor.*

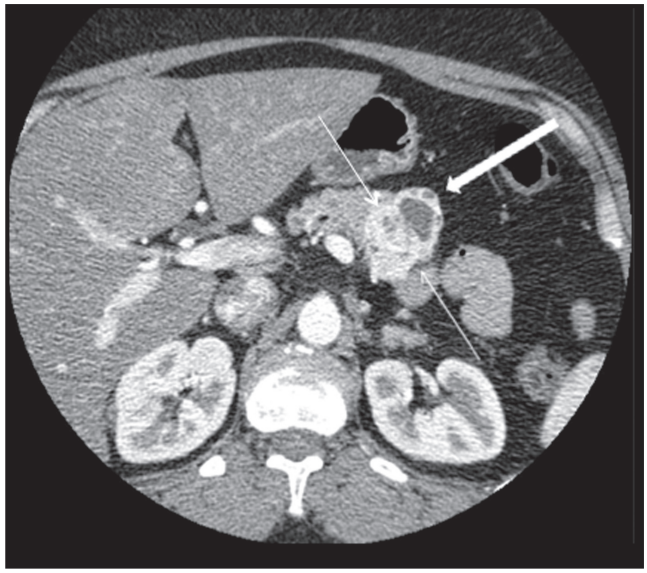

FIGURE 24. *Axial MDCT image of a 50-year-old woman shows a partially solid hyperenhancing tumor (thin white arrows) with some cystic components (thick white arrow) in a patient with Multiple Endocrine Neoplasia type 1 (MEN-1) syndrome.*

tween the celiac axis or SMA, and a patent SMV and portal vein. The definition of unresectable is ever-changing and dependent on surgeons and institutional protocols. The following are the current CT findings that are consistent with non-resectable pancreatic cancer: The first sign of unresectability is distant metastases. While MDCT will often detect larger hepatic metastases, it is limited in detecting small hepatic metastases as well as peritoneal metastatic deposits. Therefore, patients often undergo diagnostic laparoscopy for inspection of the omentum prior to surgical resection. The second sign is locally advanced arterial or venous involvement. Specific MDCT findings consistent with locally advanced unresectable pancreatic cancer include arterial encasement of the celiac trunk, hepatic artery, or SMA. Arterial encasement > 180 degree would not only make tumor resection technically impossible but is also associated with a high rate of neoplastic involvement within the mesenteric neural plexus.[8] Therefore, even if resection of the main mass were

feasible, residual disease would make it oncologically unsound; however, this concept is being challenged in a recent paper.[28] Venous involvement will only preclude potential respectability in cases where surgical reconstruction is technically impossible.[8]

There are tumors which are considered by CT criteria to be borderline resectable. Findings on CT consistent with borderline resectability include tumors that about < 180 degrees of the circumference of SMA or celiac artery (Figure 22). With short segment encasement of the common hepatic artery surgeons can often perform resection with grafting, a technically feasible, and oncologic sound technique. While clearly enlarged and distant lymph nodes are consistent with nonresectable tumors, imaging alone is inaccurate in assessment of lymph nodal involvement with metastases. Additionally, positive lymph nodes within the resection bed may be removed at the time of surgery leaving the patient with no residual disease.

Using these parameters, CT is about 95% accurate in precluding truly unresectable patients from undergoing an unnecessary attempted Whipple's procedure. However, only about 50% of cases thought to be resectable at CT are truly resectable at the time of laparotomy. In cases in which the pancreatic cancer is determined either by CT or laparotomy to be borderline but unresectable, attempts made to convert the patient to a surgical candidate by giving neoadjuvant chemotherapy and/or external beam radiation therapy and then restaging.

Pancreatic endocrine tumors

Also referred to as pancreatic islet cell tumors, these arise from pancreatic ductal cells and despite resemblance to normal islet cells histologically, they are appropriately termed as pancreatic endocrine tumors. There are 7 different types of pancreatic endocrine tumors, the most common of which are insulinomas, gastrinomas, and nonfunctional tumors (Table 7). Pancreatic endocrine tumors account for only 1% to 2% of all pancreatic neoplasms and affect only 1 in 100,000 persons. The typical age of onset is in the fourth or fifth decade. Most of these pancreatic endocrine tumors occur sporadically; however, certain syndromes, such as an MEN1, Von Hippel-Lindau, neurofibromatosis, and tuberous sclerosis, increase the likelihood of developing these tumors at a younger age. Pancreatic endocrine tumors are considered malignant based on biologic behavior (extra-pancreatic invasion or metastatic disease), not pathologic findings. The so-called functioning pancreatic endocrine tumors often produce characteristic clinical symptoms depending on the hormone excreted. Nonfunctioning pancreatic endocrine tumors produce symptoms solely due to mass-effect, such as abdominal pain, weight loss, and jaundice.[29,30]

Imaging findings

Pancreatic endocrine tumors are highly vascular lesions leading to the characteristic finding of early and avid contrast enhancement. The homogeneous enhancement is the rule for smaller lesions, while larger lesions may show areas of necrosis and cystic degeneration and have heterogeneous or only peripheral enhancement (Figures 23 and 24). Unlike pancreatic adenocarcinomas, pancreatic endocrine tumors are more conspicuous on the early arterial phase and stand out as hyperattenuating compared to the normal pancreas. Most tumors appear well circumscribed, but larger and malignant tumors may demonstrate poorly defined borders. Nonfunctioning pancreatic endocrine tumors, either because of their inherently aggressive behavior or delay in presentation, are seen with metastasis in about 70% of cases. On MRI, these tumors are T1 hypointense and characteristically, but variably, T2 hyperintense. Indium-111 octreotide scans can be used and are most helpful in identifying subtle foci of metastatic disease in patients whose tumor is known from pathologic examination to be well differentiated and contain somatostatin receptors. Pancreatic endocrine tumors may sometimes be peripancreatic, such as duodenal, in location.[30] The overall sensitivity of Indium-111 octreotide scintigraphy for diagnosis of pancreatic neuroendocrine tumors is high with 80% to 100% sensitivity for carcinoids and 60% to 90% for pancreatic NETs.

Conclusion

Optimization of scanning protocols as well as knowledge of the various maladies of the pancreas and the role of imaging in the clinical management of patients with pancreatic disorders allows the radiologist to play a large role in the diagnosis and management of inflammatory as well as neoplastic disorders of the pancreas.
